Computer Science I Insertion Sorting Lecture

 $ext{CSCI-141} \ ext{Lecture} \ rac{(1/2)}{{}_{09/22/2018}}$

1 Problem

We want to write a program that sorts a deck of cards by their numeric value.

A common approach is to start with the second card in the deck and put it in order with respect to the first, then move to the third card and put it in order with respect to the first two cards, and so on until the entire deck is sorted. This algorithm is called **insertion sort**.

We will write a function that performs an insertion sort on a list of numbers. The function will sort the list *in-place*; that means the list passed into the function will change, and the function will not create a second list.

Something to consider with sorting algorithms is their time complexity. Can we accurately measure how long it takes to sort? Clearly this depends on the organization of the data and the algorithm used. As part of the analysis and development of insertion sort, we will classify its running time with respect to the size of the data.

2 The List Python Construct

We need Python's list data type to sort lists of data. A list is a contiguous sequence of elements of arbitrary type. Another name for a list is array.

2.1 Strings versus Lists

There are a number of similarities between strings and lists of values. The table "Comparison of Python Sequence Capabilities" identifies similarities and differences between strings and lists (and tuples too).

http://www.cs.rit.edu/~csci141/pub/python-sequences.html

2.2 Lists, split() and Loops

Suppose we have this data file containing quiz grades:

```
John 80 85 93
Mary 90 93 88
Sue 91 94 87
```

We want to calculate the average for all students.

```
# create a list in which to hold the data
grades = []
# open the input file
dataFile = open( "data.txt" )
# read the file
for inputLine in dataFile:
    # read and discard the name
    elements = inputLine.split()
    name = elements [0]
    grade1 = elements [1]
    grade2 = elements [2]
    grade3 = elements [3]
    print( "Discarding name " + name )
    print( "Adding grades to list " + grade1 + " " + grade2 \
        + " " + grade3 )
    # append the grades to our list, converting to integer
    grades = grades + [int( grade1 )]
    grades = grades + [int( grade2 )]
    # or you can use the += operator
    grades += [int( grade3 )]
print( len( grades ) ) # print the number of items in list
```

```
# now that we know the number of items,
# use 'range()' to iterate over the list

sum = 0
for loopCount in range( 0, len ( grades ) ):
    sum = sum + grades[loopCount]

average = sum / len( grades )
print( "Average is " + str( average ) )
```

2.3 For and While Loops Using Indices

The Python function range() produces an *iterator* that returns values in a sequence each time code evaluates it. We often use this to generate index values in loops.

```
numbers = []
# for loop sets j to values 0, 1, ... 99 in turn.
for j in range( 0, 100 ):
    numbers += [j]

# print all even numbers using a for loop

for index in range( 0, len( numbers ) ):
    if numbers[index] % 2 == 0 :
        print( numbers [index] )

# print all even numbers using a while loop

index = 0;
while index < len( numbers ):
    if numbers[index] % 2 == 0:
        print( numbers[index] )
    index = index + 1</pre>
```

3 Analysis and Solution Design

Let's return to the problem of sorting. The marker above the card identifies a boundary between two sub-sequences: the one that is in order, and the one that is not in order. The initial ordered sequence has just one element, so it is trivially in order. Then we move an element from the unordered sequence to the ordered sequence, making sure to put that element in the correct place. When the unordered sequence is empty, the ordered sequence contains all the elements, and the sort process is complete.

We refer to moving an element from the unordered sequence to the ordered sequence as inserting because we insert the element into the ordered sequence.

There are two aspects of this insertion operation: finding the proper place to put the element, and moving all the other elements to make room. A linear search could find the proper place, and repeated swapping could move all the other elements to make room for the inserted element. Typically, these two aspects are combined, and repeated swapping is performed until the proper place is discovered.

For the picture with cards, the marker is on the first element of the unordered part of the sequence. However, we could have put it on the last element of the ordered part. It turns out that this alternative makes coding the algorithm slightly simpler.

3.1 Algorithm and Implementation

```
def swap( lst, i, j ):
    11 11 11
    swap: List NatNum NatNum -> None
    swap the contents of the list at pos i and j.
    11 11 11
    temp = lst[i]
    lst[i] = lst[j]
    lst[j] = temp
def insert( lst, mark ):
    insert: List(Orderable) NatNum -> None
    Move value at index mark+1 so that it is in its proper place.
    pre-conditions:
      lst[0:mark+1] is sorted.
    post-conditions:
      lst[0:mark+2] is sorted.
    11 11 11
    index = mark
    while index > -1 and lst[index] > lst[index+1]:
        swap( lst, index, index+1 )
        index = index - 1
def insertion_sort( lst ):
    11 11 11
    insertion_sort : List(Orderable) -> None
    Perform an in-place insertion sort on a list of orderable data.
    11 11 11
    for mark in range (len(lst) - 1):
        insert( lst, mark )
```

4 Testing (Test Cases, Procedures, etc.)

Let's develop some test cases to build confidence that the implementation works. We can check the result to see if it matches the expected answer.

1. Sorting an empty list:

```
data = []
insertion_sort( data )
data == [] ?
```

2. Sorting a list with a single element:

```
data = [10]
insertion_sort( data )
data == [10] ?
```

3. Sorting a larger list of sorted data:

```
data = [10, 20, 30, 40, 50]
insertion_sort( data )
data == [10, 20, 30, 40, 50] ?
```

4. Sorting a larger list of unsorted data:

```
data = [30, 50, 20, 10, 40]
insertion_sort( data )
data == [10, 20, 30, 40, 50] ?
```

5 Time Complexity

Now that we are more confident that our algorithm is correct, we would like to have an idea of how efficient it is.

First notice that executing the function insertion_sort entails calling the function insert N-1 times.

Hence the time complexity of insertion_sort will be $(N-1) \times T_{\texttt{insert}}(N)$, where $T_{\texttt{insert}}(N)$ is the time complexity of insert.

Let's consider the best case scenario. What is the best case for insert? If $lst[index] \le lst[index+1]$, then the loop is not executed and so the time complexity of insert is O(1), or constant time. Can it be that $lst[i] \le lst[i+1]$ for every index i such that $0 \le i < N-2$? Yes. That entails that the list is in order. In that case, the time complexity of insertion_sort is O(N).

```
best case data: [ 10, 20, 30, 40, 50, 60, 70, 80] complexity: O(N)
```

Conversely, the worst case scenario for insert occurs when lst[index] > lst[index+1] every iteration. For a single call to insert, this means that all the elements in the ordered sequence are greater than the element being inserted. Can this worst case for insert

happen for every iteration in insertion_sort? Yes, it happens if the list is in reverse order. The loop in insert then takes mark+1 iterations, but we'd like to express our answer in terms of N. A crude way to talk about the time complexity of insert is to bound mark from above. Since mark is never more than N-2, the time complexity for insert is O(N), and the time complexity for insertion_sort is $O(N^2)$. But is that analysis too pessimistic? In fact, the number of iterations performed by insert is not always N. The first time it's 1; the second time it's 2; the third time it's 3. The total number of iterations is then $1+2+\cdots+(N-1)=N(N-1)/2$ which is again $O(N^2)$.

worst case data: [80, 70, 60, 50, 40, 30, 20, 10] overall complexity: $O(N^2)$
